TWO-STAGE PROCEDURES FOR COMPARING TREATMENTS

WITH A CONTROL: ELIMINATION AT THE FIRST STAGE

AND ESTIMATION AT THE SECOND STAGE

Summary

We consider the problem of comparing a set of $p_1$ test treatments with a control treatment. This is to be accomplished in two stages as follows: In the first stage, $N_1$ observations are allocated among the $p_1$ treatments and the control, and the subset selection procedure of Gupta and Sobel (1958) is employed to eliminate "inferior" treatments. In the second stage, $N_2$ observations are allocated among the (randomly) selected subset of $p_2(\leq p_1)$ treatments and the control, and joint confidence interval estimates of the treatment versus control differences are calculated using Dunnett's (1955) procedure. Here both $N_1$ and $N_2$ are assumed to be fixed in advance, and the so-called square root rule is used to allocate observations among the treatments and the control in each stage.

Dunnett's procedure is applied using two different types of estimates of the treatment versus control mean differences: The unpooled estimates are based on only the data obtained in the second stage, while the pooled estimates are based on the data obtained in both the stages. The procedure based on unpooled estimates uses the critical point from a $p_2$-variate Student $t$-distribution, while that based on pooled estimates uses the critical point from a $p_1$-variate Student $t$-distribution. The two procedures and a composite of the two are compared via Monte Carlo simulation. It is shown that the procedure which yields shorter confidence intervals on the average depends on the expected value of $p_2$. Applicability of the proposed two-stage procedures to a drug screening problem is discussed.

Keywords and Phrases: Subset selection, Joint confidence interval estimation, Multiple comparisons with a control, Drug screening, Gupta-Sobel procedure, Dunnett procedure, Pooled estimates, Unpooled estimates.
1. Introduction

Two types of inferential goals have been proposed in the literature for use in problems involving test treatments versus control comparisons. One of these pertains to the elimination of test treatments that are "inferior" to the control treatment. The test treatments that are selected as being "superior" (or "equal") to the control treatment can then be studied more intensively in later experimentation. The other goal pertains to the joint estimation of the test treatment versus control differences with stated precision. The reasons for employing joint rather than separate estimation are explained in Bechhofer and Tamhane (1988); also see Hochberg and Tamhane (1987, Chapter 1).

These two inferential goals have been treated separately in the literature. For the first goal, Gupta and Sobel (1958) proposed a subset selection procedure (referred to herein as the GS-procedure), while for the second goal, Dunnett (1955) proposed a joint confidence interval estimation procedure (referred to herein as the D-procedure). In this paper we study a two-stage approach: The first stage uses the GS-procedure to eliminate the apparently inferior test treatments, while the second stage uses the D-procedure to estimate by joint confidence intervals (one-sided or two-sided) the performances of the retained test treatments relative to the control or placebo. In fact, we study two different procedures for second stage estimation. The first uses only the data obtained in the second stage for constructing the joint confidence intervals, and is referred to as the Not Pool D- (ND-) procedure. The second pools the data obtained in both the stages, and is referred to as the Pool D- (PD-) procedure. Relative performances of the two procedures are studied via simulation.

The outline of the paper is as follows: Section 2 introduces the notation and states the basic assumptions. Section 3 provides descriptions of the two
two-stage procedures. Section 4 discusses the so-called square root rule for allocating the total number of observations in each stage among the test treatments and the control treatment. Section 5 gives a numerical example to illustrate the procedures. Section 6 gives a comparison of the ND- and PD-procedures, and two of their variants, based on numerical and simulation results. Section 7 discusses the application of the proposed two-stage procedures in a problem of drug screening.
2. **Notation and Assumptions**

We assume that at the first (elimination) stage of experimentation there are available \( p_1 \geq 2 \) test treatments labelled 1, 2, \ldots, \( p_1 \) and a control treatment labelled 0. Let \( \{Y_{ij1}(1 \leq j \leq n_{i1})\} \) denote a random sample of size \( n_{i1} \) on the \( i \)th treatment (0\( \leq i \leq p_1 \)) with \( N_1 = \sum_{i=0}^{p_1} n_{i1} \) being the given total sample size used at the first stage. As in the usual fixed-effects one-way layout model, the random sample on the \( i \)th treatment is assumed to be drawn from a \( N(\mu_i, \sigma^2) \) distribution (0\( \leq i \leq p_1 \)). Here the \( \mu_i \) and \( \sigma^2 \) are unknown parameters. Let \( \bar{Y}_{i1} = \sum_{j=1}^{n_{i1}} \frac{Y_{ij1}}{n_{i1}} \) denote the first stage sample mean for the \( i \)th treatment (0\( \leq i \leq p_1 \)) and let

\[
S^2_{v_1} = \frac{\sum_{i=0}^{p_1} \sum_{j=1}^{n_{i1}} (Y_{ij1} - \bar{Y}_{i1})^2}{N_1-(p_1+1)}
\]

denote the first stage pooled sample variance based on \( v_1 = N_1-(p_1+1) \) degrees of freedom (d.f.).

The corresponding quantities in the second (estimation) stage are denoted by substituting subscript 2 in place of 1 in the above. Thus \( p_2 \) denotes the (random) number of test treatments retained for experimentation in the second stage. (If \( p_2 = 0 \) then there is no second stage experiment.) Without loss of generality we assume that the test treatments are labelled so that the first \( p_2 \) test treatments are retained. The total sample size \( N_2 \) for the second stage is assumed to be fixed in advance; this is allocated among the \( p_2 \) test treatments and the control treatment so that \( n_{i2} \) observations are taken on the \( i \)th treatment (0\( \leq i \leq p_2 \)) with \( N_2 = \sum_{i=0}^{p_2} n_{i2} \). Let \( \bar{Y}_{i2} = \sum_{j=1}^{n_{i2}} \frac{Y_{ij2}}{n_{i2}} \) denote the second stage sample mean for the \( i \)th treatment (0\( \leq i \leq p_2 \)) and let

3
\[ s^2_{v_2} = \frac{\sum_{i=0}^{p_2} \sum_{j=1}^{n_{12}} (Y_{ij2} - \bar{Y}_{12})^2}{N_2 - (p_2 + 1)} \]

denote the second stage pooled sample variance based on \( v_2 = N_2 - (p_2 + 1) \) d.f.

Note that both the \( n_{12} \) and \( v_2 \) are random variables, although \( N_2 = \sum_{i=1}^{p_2} n_{12} \) is fixed.

Based on symmetry considerations, we will assume throughout that \( n_{i1} = n_1 \) (say) for \( i = 1, \ldots, p_1 \) and \( n_{i2} = n_2 \) (say) for \( i = 1, \ldots, p_2 \). Thus \( N_1 = n_{01} + p_1 n_1 \) and \( N_2 = n_{02} + p_2 n_2 \).
3. Two-Stage Procedures

In this section we describe our two two-stage procedures. Both procedures have the same goals for Stage 1 and for Stage 2. The goal for Stage 1 (Goal 1) is to select a subset of the \( p_1 \) test treatments which contains all of the treatments having means \( \mu_1 \geq \mu_0 \). (These test treatments are referred to as "superior.") If this goal is achieved then a correct selection (CS) is said to have been made. The goal for Stage 2 (Goal 2) is to estimate by means of joint confidence intervals the \( p_2 \) differences \( \mu_1 - \mu_0 \) \((1 \leq i \leq p_2)\). For one-sided intervals this latter goal is referred to as Goal 2-I and for two-sided intervals it is referred to as Goal 2-II.

The probability requirement for Goal 1 is:

\[
P(\text{CS}) \geq 1 - \alpha_1 \quad \text{for all } (\mu_0, \mu_1, ..., \mu_{p_1}; \sigma^2),
\]

and that for Goal 2 is:

\[
\text{Joint Confidence Coefficient } \geq 1 - \alpha_2 \quad \text{for all } (\mu_0, \mu_1, ..., \mu_{p_2}; \sigma^2).
\]

Here \( 1 - \alpha_1 \) and \( 1 - \alpha_2 \) are prespecified numbers between 0 and 1. Notice that \( \{\mu_1, ..., \mu_{p_2}\} \) is a random subset of \( \{\mu_1, ..., \mu_{p_1}\} \), and the requirement (3.2) must be guaranteed unconditionally. This can be achieved by guaranteeing (3.2) conditionally for every possible subset.

Both two-stage procedures use the GS-procedure in Stage 1 to guarantee (3.1). The GS-procedure retains the test treatment \( i \) in the selected subset for second stage experimentation iff

\[
\overline{y}_{i1} \geq \overline{y}_{01} - g_{\nu_1} s_{\nu_1} \left( \frac{1}{n_1} + \frac{1}{n_{01}} \right)^{1/2} \quad (1 \leq i \leq p_1).
\]

Here \( g_{\nu_1} = g_{\nu_1, p_1, \rho_1, \alpha_1} \) is the 100\( \alpha_1 \) equicoordinate percentage point of the \( p_1 \)-
variate Student t-distribution with $v_1$ d.f. and associated common correlation coefficient $\rho_1 = n_1/(n_1+n_0)$. We refer to the quantity $g_{v_1} S_{v_1} (1/n_1 + 1/n_0)^{1/2}$ as the allowance associated with the GS-procedure.

The ND-procedure yields the following joint one-sided and two-sided confidence intervals, respectively, in the second stage:

\[
\{ \mu_1 - \mu_0 \geq \bar{Y}_{12} - \bar{Y}_{02} - g_{v_2} S_{v_2} \left( \frac{1}{n_2} + \frac{1}{n_0} \right)^{1/2} (1\% \text{ of } \rho_2) \} \text{ (for Goal 2-I)} \tag{3.4a}
\]

and

\[
\{ \mu_1 - \mu_0 \leq \bar{Y}_{12} - \bar{Y}_{02} + h_{v_2} S_{v_2} \left( \frac{1}{n_2} + \frac{1}{n_0} \right)^{1/2} (1\% \text{ of } \rho_2) \} \text{ (for Goal 2-II)} \tag{3.4b}
\]

Here $g_{v_2} = g_{v_2, p_2, \rho_2, \alpha_2}$ and $h_{v_2} = h_{v_2, p_2, \rho_2, \alpha_2}$ are the upper $100\alpha_2$ equicoordinate percentage points of the $p_2$-variate Student t- and $|t|$-distributions, respectively, with $v_2$ d.f. and associated common correlation coefficient $\rho_2 = n_2/(n_2+n_0)$. The quantities $g_{v_2} S_{v_2} (1/n_2+1/n_0)^{1/2}$ and $h_{v_2} S_{v_2} (1/n_2+1/n_0)^{1/2}$ are referred to as the allowances associated with the joint confidence intervals (3.4a) and (3.4b), respectively. To date the most complete and accurate tables of the critical points $g_{v}$ and $h_{v}$ have been given by Bechhofer and Dunnett (1988).

We now describe the PD-procedure. The pooled estimates on which the PD-procedure is based are calculated as follows: Let

\[
D_i = \frac{D_{i1} T_2^2 + D_{i2} T_1^2}{T_1^2 + T_2^2} \tag{3.5}
\]

denote the pooled estimate of $\mu_1 - \mu_0$ (1% sigm of $\rho_2$) where

\[
D_{ij} = \bar{Y}_{ij} - \bar{Y}_{0j} \quad (1\% \text{ sigm of } \rho_2, j=1,2) \tag{3.6}
\]

and
\[ \tau^2 = \frac{1}{n_j} + \frac{1}{n_{0j}} \quad (j=1,2). \] (3.7)

Also let
\[ S_v^2 = \frac{v_1 S_{v_1}^2 + v_2 S_{v_2}^2}{v_1 + v_2} \] (3.8)

be a pooled estimator of \( \sigma^2 \) based on \( v = v_1 + v_2 \) d.f.

Finally let
\[ \tau^2 = \left( \frac{1}{\tau_1^2} + \frac{1}{\tau_2^2} \right)^{-1} \] (3.9)

and
\[ \rho = \frac{\rho_1 \tau_2^2 + \rho_2 \tau_1^2}{\tau_1^2 + \tau_2^2}. \] (3.10)

The PD-procedure yields the following joint confidence intervals at the second stage:

\[ \{ \mu_1 - \mu_0 \geq D_1 - g_{\nu, p_1, p, \alpha_2} S_{\nu} (1 + \rho S_{\nu}) \} \quad \text{(for Goal 2-I)} \] (3.11a)

and
\[ \{ \mu_1 - \mu_0 \leq [D_1 \pm h_{\nu, p_1, p, \alpha_2} \sqrt{S_{\nu}^2}] (1 + \rho S_{\nu}) \} \quad \text{(for Goal 2-II).} \] (3.11b)

The quantities \( g_{\nu, p_1, p, \alpha_2} S_{\nu} \) and \( h_{\nu, p_1, p, \alpha_2} \sqrt{S_{\nu}^2} \) are referred to as the allowances associated with the joint confidence intervals (3.11a) and (3.11b), respectively.

The intuitive reasoning behind these "pooled" intervals is as follows: If the random nature of \( \rho_2 \) (and hence that of \( n_{02}, n_2 \) and \( v_2 \)) is ignored, then \( D_1 \) given by (3.5) is the "best" (minimum variance) pooled estimator of \( \mu_1 - \mu_0 \) among all linear combinations of \( D_{11} \) and \( D_{12} \); this minimum variance is equal to \( \sigma^2 \tau^2 \) where \( \tau^2 \) is given by (3.9). Also note that in this case the \( D_1 \) are equicorrelated with common correlation coefficient \( \rho \) given by (3.10).
We now turn to the question of whether or not the joint confidence intervals (3.4) and (3.11) associated with the ND- and PD-procedures, respectively, guarantee the probability requirement (3.2) for Goal 2. We can restrict the discussion to the one-sided intervals in each case since the same arguments apply to the two-sided intervals. For the joint one-sided confidence intervals (3.4a) associated with the ND-procedure, it is easy to see that they have an unconditional joint confidence coefficient $\geq 1-\alpha_2$. This is so because conditional on the subset selected (assuming it is nonempty), $p_2$ and hence $n_2, n_{02}$ are fixed. Therefore conditionally, the random variables

$$\frac{Y_{12} - Y_{02} - (\mu_1 - \mu_0)}{S_{\nu_2} \left( \frac{1}{n_2} + \frac{1}{n_{02}} \right)^{1/2}}$$

(1 $\leq i \leq p_2$)

have a joint $p_2$-variate Student t-distribution with $\nu_2$ d.f. and common correlation coefficient $= \rho_2 = n_2/(n_2 + n_{02})$. Hence the conditional joint confidence coefficient for the intervals (3.4a) is $1-\alpha_2$ if $p_2 \geq 1$, and it may be taken to be unity if an empty subset is selected, i.e., if $p_2 = 0$. Therefore the unconditional joint confidence coefficient is $\geq 1-\alpha_2$.

No such rigorous argument can be given for the joint one-sided confidence intervals (3.11a) associated with the PD-procedure. The reason for this is that conditional on the subset selected (assuming it is nonempty), the random variables

$$\frac{D_{11} - (\mu_1 - \mu_0)}{S_{\nu_1}}$$

(1 $\leq i \leq p_2$)

do not have a $p_2$-variate Student t-distribution even though $p_2$ and hence $n_2, n_{02}$ are fixed. This is so because conditioning on a subset selected using (3.3) restricts the $D_{11}$ to be greater than or equal to $-g_{\nu_1} S_{\nu_1} (1/n_1 + 1/n_{01})^{1/2}$ for
\(1 \leq i \leq p_2\), and hence the conditional distribution of the \(D_i\) is not \(p_2\)-variate normal. In fact, the individual \(D_i\) are not even conditionally univariate normal. It should also be noted that in (3.11a) we use the percentage point from the \(p_1\)-variate Student t-distribution even though the joint confidence statement is made concerning only \(p_2(qp_1)\) differences \(u_i - u_0\) (\(1 \leq i \leq p_2\)). This is needed to compensate for the fact that the pooled estimates \(D_i\) are based in part on the first stage data, which have already been used to select the treatments for the first stage. Note that this compensation tends to make the procedure conservative. In the simulation experiment described in Section 6, we will examine the effect of using the percentage point from the \(p_2\)-variate Student t-distribution instead of the \(p_1\)-variate.
4. Allocation of Observations

In this section we discuss the choice of \((n_{0j}, n_j)\) to be used in each stage \(j = 1, 2\). The particular choice that we recommend is based on the well-known square root allocation rule (Dunnett (1955)) which yields

\[
n_{0j} = n_0^* = \frac{N_j}{1 + \sqrt{p_j}}, \quad n_j = n_j^* = \frac{N_j}{\sqrt{p_j} \sqrt{1 + p_j}} \quad (j = 1, 2).
\]  

(4.1)

As discussed below, for stage \(j\) this choice approximately minimizes the expected allowance associated with (3.3) (for \(j = 1\)) and (3.4) (for \(j = 2\)) and exactly minimizes (ignoring the integer restrictions on \(n_{0j}\) and \(n_j\)) the common value of \(\text{var}(\bar{Y}_{ij} - \bar{Y}_{0j}) = \tau_j^2\sigma^2\) subject to given \(N_j\) and \(p_j\) and specified \(1 - \alpha_j (j = 1, 2)\).

The expected allowance associated with the GS-procedure is given by

\[
E_{v_1, p_1, \rho_1, \alpha_1} \left( \frac{1}{n_{01}} + \frac{1}{n_1} \right)^{1/2} E(S_{v_1})
\]

\[
= E_{v_1, p_1, \rho_1, \alpha_1} \left\{ (r_1 + p_1)(r_1 + 1) / r_1 \right\}^{1/2} E(S_{v_1}) / \sqrt{N_1} \quad (4.2)
\]

where we have let \(r_1 = n_{01} / n_1\) and \(\rho_1 = 1 / (1 + r_1)\). Note that the minimizing value of \(r_1\) is independent of \(\sigma\). If the ND-procedure for one-sided comparisons is used in the second stage then the criterion to be minimized is the same as (4.2) but with subscript 1 changed to 2 everywhere. If the ND-procedure for two-sided comparisons is used in the second stage then, in addition, the critical constant \(E_{v_2}\) must be replaced by \(E_{v_2}^*\). For the PD-procedure the corresponding criteria can be stated in an analogous manner, but they are functions of the first stage quantities as well. We shall indicate later in this section how the allocation (4.1) can be justified for the PD-procedure.

Minimization of the expected allowance criterion has a clear interpretation for the joint confidence interval estimation problem. For the subset selection
problem we use the same criterion because decreasing the expected allowance has the effect of decreasing the expected number of "inferior" test treatments (i.e., those having means $\mu_i < \mu_0$) included in the selected subset.

In Bechhofer, Dunnett and Tamhane (1987) we demonstrated by extensive numerical calculations that the choice $r_j = r_j^* = \sqrt{p_j}$, which gives the square root allocation (4.1), approximately minimizes the criterion (4.2) (as well as the criterion obtained by replacing $g_{v, j}$ with $h_{v, j}$). For this allocation rule, $\rho_j$ equals $1/(1+\sqrt{p_j})$. The corresponding critical constants $g_v$ and $h_v$ for $\rho = 1/(1+\sqrt{p})$ needed to implement the GS- and ND-procedures were tabulated for selected values of $p, \nu$ and $\alpha$ in the aforementioned article. (A subset of these tables may also be found in Bechhofer and Dunnett (1988).) The asymptotic (as $N_j \rightarrow \infty$) optimality of (4.1) for joint confidence interval estimation was shown by Bechhofer (1969) for one-sided comparisons and by Bechhofer and Nocturne (1972) for two-sided comparisons.

As we pointed out, the square root allocation rule (4.1) exactly minimizes $\text{var}(\bar{Y}_{1j} - \bar{Y}_{0j}) = \tau_j^2 \sigma^2$ subject to given $N_j$ and $p_j$ ($j = 1, 2$). (This results in only approximate minimization of the expected allowance criterion because the critical constants $g_{v, j}$ and $h_{v, j}$, which also are functions of $r_j = n_{0j}/n_j$ through $\rho_j = 1/(1+r_j)$, do not vary much with $p_j$ for small $\alpha_j$ ($j = 1, 2$).) Therefore for stage $j = 2$, (4.1) exactly minimizes $\tau_j^2 \sigma^2$ for any given $\tau_1^2$, and $N_2$ and $p_2$.

Now the expected allowance (conditioned on $p_2$) associated with the PD-procedure (3.11) is proportional to $\tau$; moreover, the critical constants $g_v, p_1, \rho, \alpha_2$ and $h_v, p_1, \rho, \alpha_2$ are relatively insensitive to the choice of $r_2$. Therefore it follows that (4.1) also approximately minimizes the expected allowance associated with the PD-procedure.

In practice, the $(n_{0j}^*, n_j^*)$ values given by (4.1) must be rounded to one of the nearest integer values, which are
(n_{0j}, n_j) = \begin{cases} 
(N_j - p_j [n_j^*], [n_j^*]) & (j = 1, 2), \\
(N_j - p_j [n_j^{*+1}], [n_j^{*+1}]) & (4.3b)
\end{cases}

where \([x]\) denotes the integer part of \(x\). The choice between (4.3a) and (4.3b) should be based on the minimum expected allowance criterion. To make this comparison the critical constants associated with the two allocations (4.3a) and (4.3b) with their respective \(p\)-values are needed. Linear interpolation with respect to \(1/(1-p)\) in the tables of Bechhofer and Dunnett (1988) is recommended for this purpose if the exact values are not readily available.
5. Numerical Example

Suppose that a pharmaceutical laboratory has identified 20 chemical compounds which it wishes to test against an existing standard drug (or placebo). The testing is to be done in two stages. The purpose of the first stage is to eliminate those compounds which are indicated as being "inferior" to the control compound so that more observations can be allocated in the second stage to the compounds retained which are presumably the "superior" ones. Suppose that 70 animals are available for each stage of testing.

For the first stage it is desired to design an efficient experiment so that with probability at least 0.90 the selected subset will contain all test compounds at least as good as the control compound; thus \(1 - \alpha_1 = 0.90\). Here \(p_1 = 20\), \(N_1 = 70\); hence there will be \(v_1 = N_1 - (p_1 + 1) = 70 - 21 = 49\) d.f. available for estimating \(\sigma^2\). From (4.1) we see that the asymptotically optimal allocation is

\[
n^*_0 = \frac{N_1}{1 + \sqrt{p_1}} = \frac{70}{1 + \sqrt{20}} = 12.79 \quad \text{and} \quad n^*_1 = \frac{N_1}{\sqrt{p_1(1 + \sqrt{p_1})}} = \frac{70}{\sqrt{20(1 + \sqrt{20})}} = 2.86.
\]

From (4.3) the corresponding rounded pairs of integers are given by \((n^*_0, n^*_1) = (30, 2)\) and \((10, 3)\); the associated \(p_1\)-values are 0.0625 and 0.2308, respectively.

The corresponding critical constants are \(g_{49,20,.0625,.10} = 2.633\) and \(g_{49,20,.2308,.10} = 2.572\). The expected allowance is proportional to

\[
2.633(1/30 + 1/2)^{1/2} = 1.923 \quad \text{if} \quad (n^*_0, n^*_1) = (30, 2), \quad \text{and} \quad 2.572(1/10 + 1/3)^{1/2} = 1.693 \quad \text{if} \quad (n^*_0, n^*_1) = (10, 3).
\]

Thus the latter choice is preferred. (In fact, the only other choice for \((n^*_0, n^*_1)\) is \((50, 1)\) which leads to \(p_1 = 0.0196\) and \(g_{49,20,.0196,.10} = 2.644\). This choice is clearly inferior to either of the other two. Hence the square root rule indeed yields the overall optimum allocation in this case.)

Thus in the first stage, 10 observations will be taken on the control compound and 3 observations on each of the 20 test compounds. Then those test
compounds whose sample means $\bar{Y}_{11}$ are no less than $\bar{Y}_{01} - 1.693S_{\bar{y}_{1}}$ will be retained for further experimentation.

Now suppose that 15 compounds are eliminated in the first stage, and 5 are retained in the selected subset. In the second stage it is desired to obtain, say, 95% joint one-sided confidence interval estimates of the five differences $\mu_1 - \mu_0$ (1≤i≤5); thus $1 - \alpha_2 = 0.95$. Here $p_2 = 5$, $N_2 = 70$; hence there will be $v_2 = N_2 - (p_2 + 1) = 70 - 6 = 64$ d.f. available for estimating $\sigma^2$ from the second stage. From (4.1) we obtain

\[ n_{02}^* = \frac{N_2}{1 + \sqrt{p_2}} = \frac{70}{1 + \sqrt{5}} = 21.63 \quad \text{and} \quad n_{2}^* = \frac{N_2}{\sqrt{p_2(1 + \sqrt{p_2})}} = \frac{70}{\sqrt{5(1 + \sqrt{5})}} = 9.67. \]

Using (4.3) we find that the corresponding rounded pairs of integers are

$(n_{02}, n_{2}) = (25, 9)$ and $(20, 10)$; the associated $p_2$-values are 0.2647 and 1/3, respectively. Following the same steps as taken earlier, we find that $(n_{02}, n_{2}) = (20, 10)$ is the preferred choice for the one-sided ND-procedure, the necessary critical constant in this case being $q_{64, 5, 1/3, .05} = 2.329$. This same choice $(n_{02}, n_{2}) = (20, 10)$ is also preferred for the two-sided ND-procedure, the necessary critical constant in this case being $h_{64, 5, 1/3, .05} = 2.616$.

Now suppose that it is desired to employ the PD-procedure at the second stage. Using the square root allocation rule we are again led to choosing between $(n_{02}, n_{2}) = (25, 9)$ or $(20, 10)$. The corresponding $\tau^2$-values are 0.1511 and 0.1500, respectively, and the $p_2$-values are 0.2647 and 1/3, respectively.

Assuming that $(n_{01}, n_{1}) = (10, 3)$ is used in the first stage, we have $\tau^2_1 = (1/10 + 1/3) = 0.4333$ and $\rho_1 = 0.2308$. Applying (3.9) and (3.10) we obtain

$(\tau^2, \rho) = (0.1120, 0.2558)$ for $(n_{02}, n_{2}) = (25, 9)$ and $(\tau^2, \rho) = (0.1114, 0.3070)$ for $(n_{02}, n_{2}) = (20, 10)$. Since the latter choice yields a smaller $\tau^2$ and larger $\rho$, it is clear that it will yield the smaller expected allowance. The critical constants needed to implement the PD-procedure for this choice of $(n_{02}, n_{2})$ are
8_{13,20,.3070,.05} = 2.784 and h_{13,20,.3070,.05} = 3.039 for one-sided and two-sided joint intervals, respectively; here the pooled d.f. are \( \nu = 49+64 = 113. \)
6. A Comparison of Procedures

In this section we compare the performances of the ND- and PD-procedures via Monte Carlo simulation. We also study two variants of these two procedures for making joint confidence statements at the second stage. The rationale behind these variants will become clear after we make a preliminary comparison between the ND- and PD-procedures. For convenience, in this section we will refer to these two procedures as $\mathcal{P}_1$ and $\mathcal{P}_2$, respectively.

It is clear from the description of $\mathcal{P}_2$ that it will tend to be conservative if the true number, say $q (\leq p_1)$, of "superior" test treatments is small relative to $p_1$. This is so because $\mathcal{P}_2$ uses the critical point from the $p_1$-variate Student t-distribution when, in fact, only $p_2 (\leq p_1)$ joint confidence statements about apparently "superior" test treatments are made. A natural question to ask is whether a procedure that uses $\nu, p_2, \rho, \alpha_2$ in place of $\nu, p_1, \rho, \alpha_2$ in (3.11a) will still guarantee the probability requirement (3.2) for Goal 2-I. We refer to such a procedure as $\mathcal{P}_3$. We will show by simulation that $\mathcal{P}_3$ does not guarantee (3.2) in all cases, i.e., it can be liberal.

Based on the above discussion we can surmise that $\mathcal{P}_2$ will yield a wider allowance than $\mathcal{P}_1$ if $p_2/p_1$ is small and vice versa. We will now compare the one-sided allowances for the two procedures for $p_1 = 20$, $p_2 = 1\, (1)\, 10\, (2)\, 20$, $N_1 = 70$, $N_2 = 70$, $(n_{01}, n_1) = (10, 3)$ and thus $(\nu_1, \rho_1) = (0.4333, 0.2308)$, $\nu_1 = 49, \nu_2 = 70-(p_2+1)$ and $1-\alpha_2 = 0.95$. In this comparison, for each given $p_2$, $(n_{02}, n_2)$ is chosen using the square root allocation rule given in Section 4. Furthermore, the sampling variations in $S_{v_2}$ and $S_v$ are ignored because $\nu_2$ and $\nu = \nu_1 + \nu_2$ are large; both $S_{v_2}$ and $S_v$ are taken to be equal to unity, which is the assumed value of $\sigma$. The results are presented in Table I. The $\mathcal{P}_3$-allowances also are included in this table for additional information.

From Table I we see that among the three procedures, $\mathcal{P}_3$ yields the smallest allowance for all values of $p_2$; however, this is at the expense of not

</table>
guaranteeing (3.2) in all cases, as noted above. Between $\mathcal{P}_1$ and $\mathcal{P}_2$, the former yields the smaller allowance for $p_2 \leq 5$ and the latter yields the smaller allowance for $p_2 > 5$. This observation suggests an adaptive composite procedure $\mathcal{P}_4$ which uses $\mathcal{P}_1$ for making the joint confidence statements at the second stage if $p_2 \leq 5$ and which uses $\mathcal{P}_2$ if $p_2 > 5$. (More generally, the precise value of $p_2$ at which the $\mathcal{P}_2$-allowance becomes smaller than the $\mathcal{P}_1$-allowance will depend on the values of $p_1$, $N_1$, $N_2$ and whether the square root or some other allocation rule is employed at each stage.)

In summary, the following four procedures, all of which use the GS-procedure for subset selection in the first stage, were compared in our simulation study:

$\mathcal{P}_1$: ND-procedure.
$\mathcal{P}_2$: PD-procedure.
$\mathcal{P}_3$: PD-procedure which uses $g_{\nu, p_2, \rho, \alpha_2}$ instead of $g_{\nu, p_1, \rho, \alpha_2}$ in (3.11a).
$\mathcal{P}_4$: Uses 1 if $p_2 \leq 5$ and 2 if $p_2 > 5$.

The procedures were simulated under seven different $\mu_i$-configurations for $p_1 = 20$. The $\mu_i$-configurations were chosen so as to cover three different values of $q$, the true number of "superior" test treatments ($q = 5, 10$ and 20). Without loss of generality, throughout we assumed $\mu_0 = 0$ and $\sigma^2 = 1$. The $\mu_i$-values for "superior" test treatments were taken to be equal to $\mu_0$, but the $\mu_i$-values for "inferior" test treatments were varied over the range $-1$ to $-4$ in different combinations. The seven configurations are listed below.

Config.1: $\mu_1 = \ldots = \mu_{20} = 0$ ($q = 20$)
Config.2: $\mu_1 = \ldots = \mu_{10} = -1, \mu_{11} = \ldots = \mu_{20} = 0$ ($q = 10$)
Config.3: $\mu_1 = \ldots = \mu_{10} = -2, \mu_{11} = \ldots = \mu_{20} = 0$ ($q = 10$)
Config.4: $\mu_1 = \ldots = \mu_{15} = -2, \mu_{16} = \ldots = \mu_{20} = 0$ ($q = 5$)
Config.5: $\mu_1 = \ldots = \mu_8 = -4, \mu_9 = \ldots = \mu_{15} = -2, \mu_{16} = \ldots = \mu_{20} = 0$ ($q = 5$)
Config. 6: $\mu_1 = \ldots = \mu_{15} = -3$, $\mu_{16} = \ldots = \mu_{20} = 0 \ (q = 5)$
Config. 7: $\mu_1 = \ldots = \mu_{15} = -4$, $\mu_{16} = \ldots = \mu_{20} = 0 \ (q = 5)$.

For each configuration a total of 50,000 independent replications were performed, which constituted one simulation run. Each replication consisted of two stages: In the first stage the mutually independent random variables $\bar{Y}_{01} - N(\mu_0, \sigma^2/n_{01})$, $\bar{Y}_{11} - N(\mu_1, \sigma^2/n_1)$ (1.1 $\xi \xi \xi p_1$) and $S^2_{v_1} - \sigma^2 \chi^2_{v_1}/v_1$ were generated and the GS-procedure (3.3) was applied to select a subset of $p_2$ test treatments. Here we used $N_1 = 70$ with the associated square root allocation $(n_{01}, n_1) = (10, 3)$ and $1-\alpha_1 = 0.90$. As noted in Section 5, in this case we have $v_1 = 49$, $p_1 = 0.2308$ and $849, 20, 2308, 10 = 2.633$. In the second stage the mutually independent random variables (which are independent of the first stage random variables) $\bar{Y}_{02} - N(\mu_0, \sigma^2/n_{02})$, $\bar{Y}_{12} - N(\mu_1, \sigma^2/n_2)$ (1.1 $\xi \xi \xi p_2$) and $S^2_{v_2} - \sigma^2 \chi^2_{v_2}/v_2$ were generated and each of the four procedures was applied to the resulting data to construct one-sided joint confidence intervals for $\mu_1 - \mu_0$ for the selected test treatments. For a given procedure the proportion of replications that resulted in the correct coverage of all of the $\mu_1 - \mu_0$ for the selected test treatments was used as an estimate of the joint confidence coefficient of that procedure. In the second stage we used $1-\alpha_2 = 0.95$ and $N_2 = 70$. For each given $p_2$ (1.1 $\xi \xi \xi p_2 \leq 20$) we used the square root allocation $(n_{02}, n_2)$ given in Table I such that $n_{02} + p_2 n_2 = N_2 = 70$. These allocations and the associated critical constants needed to implement the four procedures were determined in advance and stored in memory, so that they did not have to be recomputed each time.

All simulation runs were performed on McMaster University's VAX-8600 computer using a Fortran program. IMSL subroutines GGNPM and GGCCHS were used to generate the normal and chi-square random variables, respectively. A single simulation run consisting of 50,000 replications of the four procedures took approximately 5 minutes of CPU time at a rate of $\$20$ per hour. The simulation
results are reported in Table II.

</table>

The primary quantities of interest in Table II are the estimated joint confidence coefficients of the procedures $\hat{P}_1$. These are to be compared with the nominal level $1-\alpha_2 = 0.95$. In making this comparison it must be kept in mind that the standard error of each estimate is approximately $(.05 \times .95 / 50,000)^{1/2} = 0.0010$. Thus the estimated values would be expected to lie in the interval $0.95 \pm 2 \times 0.0010$ if the corresponding joint confidence coefficients are controlled at the nominal level of 0.95. Using this criterion we find that $\hat{P}_1$ controls the joint confidence coefficient quite accurately at the nominal level; this is, of course, to be expected in view of the proof of this fact given in Section 3.

We next note that for large values of the expected subset size, $E(p_2)$, $\hat{P}_2$ controls the joint confidence coefficient accurately at the nominal level but the conservatism of $\hat{P}_2$ increases with decreasing $E(p_2)$-values. $\hat{P}_2$ is extremely conservative for configurations 5, 6 and 7, which involve small values of q and large negative $\mu_1$-values for the "inferior" test treatments. These latter configurations result in small expected subset sizes. This behavior of $\hat{P}_2$ is to
be anticipated in view of our previous discussion.

Next note that $\Phi_3$ is liberal under all configurations except under configuration no. 1 and possibly under configuration no. 2. Thus $\Phi_3$ is not an acceptable procedure.

Finally $\Phi_4$ appears to control the joint confidence coefficient in most cases, but under one configuration (config. no. 6) it is liberal. Thus there is some question about its validity under all configurations.

As a matter of additional interest, in Table III we give the simulation estimates for each $\Phi$ of the probability of the joint event that a correct selection is made in the first stage (i.e., all "superior" test treatments are included in the subset) and all the $\mu_1 - \mu_0$ for the selected test treatments are covered by their respective confidence intervals. We refer to this probability as the overall probability of no error.

**Table III**

**Simulation Estimates of the Overall Probability of No Error**

</table>

The estimates in Table III may be compared with the nominal value $(1-\alpha_1) \times (1-\alpha_2) = 0.90 \times 0.95 = 0.855$, which is the overall probability of making no error under configuration no. 1 (the least favorable configuration for the GS-procedure) if the inferences in the two stages were statistically independent.
However, this independence holds only for $\theta_1$. We note that the probabilities for all the $\theta_1$ are within two standard errors ($= 2\times(0.855\times0.145/50,000)^{1/2} \approx 0.0032$) of the nominal value under configuration no. 1. For other configurations, the achieved probabilities for all the $\theta_1$ are strictly higher than the nominal value because the first stage GS-procedure achieves $P(CS) > 1-\alpha_1 = .90$ under these more favorable configurations.

In conclusion, if the unknown proportion of "superior" test treatments (viz. $q/p_1$) is expected to be large (say, at least one quarter of the total number of test treatments are expected to be "superior") than $\theta_2$ is the preferred procedure; otherwise $\theta_1$ is the preferred procedure. $\theta_4$ provides a compromise between the two procedures, and is a good practical alternative. $\theta_3$ is not an acceptable procedure.

In practice it would seem wasteful not to pool the data from the two stages. Therefore, in future research it would be desirable to develop a less conservative version of the PD-procedure for small $p_2$-values, which can be recommended in all situations.
7. Application to Drug Screening

Drug screening is generally an on-going program consisting of a series of experiments in each of which perhaps 20 to 30 chemical compounds are tested for some specific type of activity. The total number of compounds tested is very large, but the number of compounds included in each experiment depends on the available laboratory facilities and resources. The purpose of the screening is to eliminate the compounds which have little or no activity. A false positive is a compound which, although not having the desired level of activity, nevertheless by chance gives a result on the screening test that falls in the "acceptable" range. Even though the accept/reject rule used in the screening test may be designed to have a very small probability of such an occurrence, the actual number of false positives that accrue over a period of time may be quite large, perhaps even exceeding the number of true positives. Hence, before proceeding further with more definitive testing of the compounds that have been identified by the initial screening procedure, it may be desirable to carry out a special experiment to eliminate the false positives and obtain precise estimates of the biological activity of the compounds indicated as being true positives.

We suggest that the two-stage approach described in this article may be appropriate for such an experiment. The purpose of the first stage (GS-procedure) would be to eliminate most of the false positives accrued in previous screening tests, while the purpose of the second stage would be to estimate the activity levels of the retained treatments in the first stage relative to a reference standard. For the latter, a known active compound would be used if one were available; otherwise an inactive control could be used.

An important design problem now arises, namely, how to allocate a fixed total amount of resources (e.g., a fixed total number of animals available to carry out the entire experiment) between the two stages. In other words, what
are the "optimal" values of \( N_1 \) and \( N_2 \) for fixed given \( N = N_1 + N_2 \). This problem is not easy to formulate mathematically. A reasonable formulation would involve the expected number of "inferior" test treatments retained at the first stage, and errors of estimation at the second stage as measured by the expected values of the allowances of joint confidence intervals (for specified values of \( 1 - \alpha_1 \) and \( 1 - \alpha_2 \)). The solution would depend on unknown parameters, e.g., the actual proportion of "inferior" test treatments. For instance, if this proportion were thought to be small, it might be desirable to omit the first stage entirely and allocate all the available experimental resources to the second stage.

The goal associated with the GS-procedure (Goal 1) states that all test compounds with means \( \mu_i \geq \mu_0 \) be included in the selected subset. (If an active compound is used as a reference standard then \( \mu_0 \) would be its unknown mean. However, if an inactive control is used as a reference standard then \( \mu_0 \) should be its mean plus a specified constant \( \delta > 0 \); here \( \delta \) is the minimum threshold that the mean of the test compound must exceed that of the inactive control in order for it to be considered "superior." ) In practice, the number of such compounds and also the number of compounds with means \( \mu_i < \mu_0 \) is unknown. The constants necessary to implement the GS-procedure are derived under the so-called "least favorable" configuration in which all test compounds are assumed to have means \( \mu_i = \mu_0 \) (\( \forall i \neq 1 \)). However, this assumption may be much too conservative if the experimenter has reason to believe that a number of the compounds actually have mean values \( \mu_i < \mu_0 \). In this case, it may be modified as follows: Prior to the start of experimentation the experimenter may be prepared to state an upper bound \( m_1 \leq \rho_1 \) on the number of true positive test compounds. Then the asymptotically optimal allocation is still given by (4.1) but the critical constant to be used in the associated GS-procedure (3.3) is reduced from \( g_{v_1, p_1, \rho_1, \alpha_1} \) to \( g_{v_1, m_1, \rho_1, \alpha_1} \) where \( \rho_1 \) still equals \( 1/(1 + \sqrt{\rho_1}) \). In particular,
if \( m_1 = 1 \) then this latter critical constant equals \( t_{v_1, \alpha_1} \) -- the upper \( \alpha_1 \)-point of the univariate Student's t-distribution with \( v_1 \) d.f. Tables of \( g_{v_1, m_1, p_1, \alpha_1} \) for \( m_1 = 2, \ldots, p_1 - 1 \) are not available. The case \( m_1 = p_1 \) dealt with in the present paper would correspond to the situation in which a series of structurally related compounds are submitted together for testing. However, even in this situation the experimenter may not require that the selected subset contain all "superior" compounds; i.e., he may be satisfied with selecting only a specified fraction.

Another difficulty with the use of the GS-procedure is that since the number of treatments in the selected subset is random, problems may arise in the second stage (the D-procedure) if the total amount of experimentation (\( N_2 \)) that can be carried out in that stage is fixed in advance, as is assumed in the present article. Therefore one may wish to use a procedure with a prespecified upper bound on the number of test treatments in the selected subset as proposed by Santner (1975) for a different problem.
